CNB WORKING PAPER SERIES

The Working Paper Series of the Czech National Bank (CNB) is intended to disseminate the results of the CNB's research projects as well as the other research activities of both the staff of the CNB and collaborating outside contributor, including invited speakers. The Series aims to present original research contributions relevant to central banks. It is refereed internationally. The referee process is managed by the CNB Research Department. The working papers are circulated to stimulate discussion. The views expressed are those of the authors and do not necessarily reflect the official views of the CNB.

Distributed by the Czech National Bank. Available at <http://www.cnb.cz>.

The Impact of Capital Measurement Error Correction on Firm-Level Production Function Estimation

Kamil Galuščák and Lubomír Lízal*

Abstract

Based on a large panel of Czech manufacturing firms, we estimate firm-level production functions in 2003–2007 using the Levinsohn and Petrin (2003) and Wooldridge (2009) approaches, correcting for the measurement error in capital. We show that measurement error plays a significant role in the size of the estimated capital coefficient. The capital coefficient estimate approximately doubles (depending on the particular industry) when we control for capital measurement error. Consequently, while the majority of industries exhibit constant or (in)significantly decreasing returns to scale when the standard methods are used, increasing returns cannot be rejected in some industries when the estimation is corrected for capital measurement error.

JEL Codes: C23, C33, D24, O47.

Keywords: Capital, firm-level data, measurement error.

Nontechnical Summary

Relating production inputs and productivity to aggregate output by means of the production function is necessary for understanding the driving sources of economic growth. Looking at the microeconomic evidence, the estimation of firm-level production functions is a non-trivial exercise owing to simultaneity bias between unobserved productivity shocks and inputs used in production. Among the popular methods used to address simultaneity bias, Levinsohn and Petrin (2003) rely on intermediate input as a proxy to invert out unobserved productivity from the regression residual in a two-step estimation, while Wooldridge (2009) proposes a one-step estimation.

Production function estimates may be affected by measurement issues. In particular, capital is often recorded in the available datasets in acquisition (book-keeping) values that do not reflect the amount of capital used in production. The previous literature relies either on a kind of perpetual investment method where the capital is derived from book-keeping values and depreciation, or on the stock of fixed assets deflated by the industry-wide average deflator. Capital is thus measured with an error which should be addressed in the estimation of production functions.

To address the capital measurement problem, we estimate production functions using the Wooldridge (2009) approach, accounting for capital measurement error by using appropriate instruments for capital. We also modify the Levinsohn and Petrin (2003) approach to estimate production functions implemented in Stata (see Petrin, Poi, and Levinsohn, 2004), while modification for other measurement errors in variables would be a straightforward extension.

In particular, we estimate firm-level production functions in 2003–2007 using a large panel of Czech manufacturing firms with 20 or more employees containing balance sheet and income statement information. As the dataset contains mainly financial data, we complement the dataset with firm-level information on material consumption in physical units. The advantage of our data is that all intermediate inputs are reported in physical units so that there is no problem with prices and deflating, which might be yet another source of measurement error.

We show that the measurement error in capital is a substantial problem that affects production function estimates. Depending on the particular industry, the estimated capital coefficient approximately doubles when we control for capital measurement error. Consequently, while the majority of industries exhibit constant or (in)significantly decreasing returns to scale when the standard Wooldridge (2009) or Levinsohn-Petrin (2003) routines are used, increasing returns cannot be rejected in some industries when the capital measurement error is corrected for.

1. Introduction

Relating aggregate output to productivity and production factors by means of production function is the basis for understanding the sources of economic growth.¹ At the microeconomic level, however, estimating firm-level production functions is a non-trivial exercise owing to simultaneity bias caused by the relationship between unobserved productivity shocks and inputs used in production. Hence, it entails similar problems as the estimation of matching functions in labor economics (see, for example, Galuščák and München, 2007).

A number of methods have been developed to address the simultaneity bias in production function estimation. While Blundell and Bond (2000) use method of moments techniques, other approaches rely on finding proxy variables for productivity shocks, which are used to invert out productivity from the regression residual in a two-step estimation (Olley and Pakes, 1996; Levinsohn and Petrin, 2003). Wooldridge (2009) proposes a one-step estimation implemented in a generalized method of moments framework.

Another problem in production function estimation is posed by measurement issues. While labor as a measure of production input is available in datasets used in the estimation of production functions, the stock of capital is difficult to measure. Capital is often recorded in acquisition (book-keeping historical) values that reflect neither the amount of capital used in current production nor its market valuation. Levinsohn and Petrin (2003) as well as many other researchers use a kind of perpetual investment method where the capital is derived from book-keeping values and depreciation.² Another approach uses real capital as the stock of fixed assets deflated by the average deflator within industries (see, for example, Geršl, Rubene, and Zumer, 2007).³ However, all these studies treat capital, after these adjustments, as correctly measured and recorded. We argue that capital is measured with an error which should be, and needs to be, addressed in production function estimation.

Recent research into production functions for the Czech economy has focused on the macroeconomic approach,⁴ while the literature on the estimation of individual firm-level production functions is scant. Lizal, Singer, and Baghdasarian (2001) estimate the production functions of Czech industrial firms in the mid-1990s as a by-product of the investment and labor

¹ In the CNB's (Czech National Bank) core forecasting model, the key concept is implied aggregate technology, which determines the steady-state growth of the economy (Andrle et al., 2009). Similarly, in the previously used CNB quarterly projection model, the long-term trend was captured by potential output growth (Coats, Laxton, and Rose, 2003). Both concepts of long-term economic growth, while different in nature, may be related to aggregate total factor productivity in sectors.

² The main problem in this approach is that the depreciation rate and the initial stock of capital are unknown; see Hernández and Mauleón (2002, 2005) for suggestions on how to estimate the stock of capital. Furthermore, Hájková (2008) shows that capital services better account for productive capital input in production than the capital stock net of depreciation and that the net capital stock underestimates the contribution of capital input to production particularly in fast-growing Czech industries.

³ Ornaghi (2006) shows that the use of common (industry-wide) price deflators leads to misleading results in the estimation of production function parameters.

⁴ Dybczak et al. (2006) apply the aggregate production function to approximate the path of potential output in the Czech economy using trend total factor productivity. Deriving production functions in key sectors during 1995–2005, they decompose the total factor productivity growth into intra-industry, inter-industry, and reallocation effects.

adjustment cost function. They find that Czech industrial firms exhibit decreasing returns to scale.⁵ Individual production functions are also estimated in Geršl, Rubene, and Zumer (2007), who investigate the inflows of foreign direct investment into Central and Eastern European countries, focusing on the analysis of productivity spillovers. Using firm-level data on manufacturing industries for the period 2000–2005, they estimate the total factor productivity of domestic firms using the Levinsohn and Petrin (2003) approach. Kátay and Wolf (2008) construct a proxy for capacity utilization, allowing them to estimate firm-level total factor productivity that is clean of cyclical capacity utilization, and use these estimates in the decomposition of value added growth in Hungarian manufacturing industries in 1993–2004 into the contributions of primary inputs and total factor productivity growth.

Each production function for an individual firm is an approximation of an underlying production function around the point of current operation. Industries use different technologies and the individual firm technologies may have a different shape than the aggregate overall industry production function. For an illustration of this feature, we refer the reader to Earnhart and Lízal (2006), and mainly Earnhart and Lízal (2008), who examine the link between production and pollution emissions from the perspective of the shape of the relationship and find that certain industries exhibit the commonly assumed linear dependence of emissions on production while other industries show a more complex pattern. In particular, both the metals sector and the energy sector enjoy economies of scale of emissions vis-à-vis production at lower production levels, while facing diseconomies of scale at higher production levels. In contrast, the chemicals sector encounters neither economies nor diseconomies of scale, with an apparent proportional relationship between emissions and production.

In this paper, we correct for measurement error in capital in the estimation of production functions. We do so by using appropriate instruments for capital in the Wooldridge (2009) method. We also modify the Levinsohn and Petrin (2003) approach (LP hereafter) to estimating production functions, which is implemented in Stata (see Petrin, Poi, and Levinsohn, 2004), correcting for the measurement error in capital. Using a two-stage approach, we generate predicted values of capital in the first stage of the LP routine and use these predictions as the capital data input in the LP method together with the prediction error of the capital. We also modify the current LP non-parametric bootstrap used to obtain the standard errors of the coefficient estimates to account for the instrumental variable regression in the first stage. We demonstrate that measurement error correction significantly raises the coefficient estimates of capital, leading to a situation where increasing returns cannot be rejected in some manufacturing industries.

The paper is organized as follows. Section 2 describes the methodology, focusing on the LP and Wooldridge (2009) approaches and describing the correction in measurement error in capital. Section 3 describes the data, while in Section 4 we report the results. Section 5 concludes the paper.

⁵ Returns to scale in individual manufacturing industries in Hungary and Bulgaria in 1995–2001 are estimated in Dobrinsky et al. (2008) and used in the estimation of mark-ups. In particular, constant returns are rejected for most manufacturing industries in Bulgaria in favor of decreasing returns and approximately for a half of industries in Hungary in favor of increasing returns. Dobrinsky et al. (2008) argue that the lower returns to scale in Bulgaria than in Hungary are consistent with the different transition paths of these two economies. They also find that small firms often operate with decreasing returns to scale.

2. Estimation Strategy

To illustrate the identification of production functions, let us consider a standard Cobb-Douglas production function (omitting firm subscripts)

$$y_t = \beta_0 + \beta_k k_t + \beta_l l_t + \omega_t + \varepsilon_t, \quad (1)$$

where y_t is the log of real value added (or revenue), k_t is the log of quasi-fixed input (real capital), l_t is the log of freely variable input (labor),⁶ and ε_t is an iid error term. The productivity shock ω_t is unobservable to the econometrician but known to the firm, which decides on production and factor utilization. The unobserved productivity shock ω_t is therefore correlated with factor inputs, so that estimating (1) with ordinary least squares without controlling for ω_t yields biased parameter estimates.

The simultaneity problem can be solved using method of moments techniques (Blundell and Bond, 2000), which involve differencing. While differencing removes the unobserved individual productivity shock, it also removes much of the variation in the explanatory variables. In addition, Wooldridge (2009) shows that the instruments are weakly correlated with the differenced explanatory variables, leading to bias in finite samples. Other literature therefore focuses on finding proxy variables for productivity shocks and then uses the information in the proxies to invert out productivity from the residual. For example, Olley and Pakes (1996) use investment as a proxy for the unobserved productivity shock in a two-step estimation of production functions. On the other hand, Levinsohn and Petrin (2003) argue that many firms have zero-investment observations, leading to efficiency loss in the estimation using the Olley and Pakes approach, while non-convex adjustment costs may also affect the responsiveness of investment to the shocks. We also add that the firm may even wish to disinvest and such cases are not directly distinguishable from zero investment observations and one would need to employ a switching regression framework. As a solution, Levinsohn and Petrin still rely on a two-step approach, but use intermediate inputs such as materials or energy to invert out the unobserved productivity shock.

In the Levinsohn and Petrin approach, demand for the intermediate input is assumed to depend on the firm's capital k_t and the productivity shock ω_t :

$$m_t = f(k_t, \omega_t). \quad (2)$$

Under mild assumptions about the firm's production technology, Levinsohn and Petrin demonstrate that the intermediate demand function (2) is monotonically increasing in ω_t so that it can be inverted as

$$\omega_t = g(k_t, m_t). \quad (3)$$

The final identification restriction assumes that ω_t follows a first-order Markov process

⁶ Given these assumptions, one could use the equality of the marginal product of labor and the price of labor (wage) as another identification restriction. However, such restriction is not used in Levinsohn and Petrin (2003) or Wooldridge (2009).

$$\omega_t = E[\omega_t | \omega_{t-1}] + \xi_t, \quad (4)$$

where ξ_t is an innovation to productivity that is uncorrelated with quasi-fixed capital k_t , but not necessarily with labor l_t .

Petrin, Poi, and Levinsohn (2004) implement in Stata the method of Levinsohn and Petrin, based on third-order polynomial approximation of the unknown function in (3). Using (3), equation (1) becomes

$$y_t = \beta_0 + \beta_k k_t + \beta_l l_t + g(k_t, m_t) + \varepsilon_t \quad (5)$$

or

$$y_t = \beta_l l_t + \phi(k_t, m_t) + \varepsilon_t, \quad (6)$$

where

$$E(\varepsilon_t | l_t, k_t, m_t) = 0 \quad (7)$$

and

$$\phi(k_t, m_t) = \beta_0 + \beta_k k_t + g(k_t, m_t). \quad (8)$$

In (6), a third-order polynomial approximation in k_t and m_t is substituted in place of Φ_t and the parameter β_l is estimated using ordinary least squares. This completes the first stage of the Levinsohn-Petrin routine.

In the second stage, the coefficient β_k is identified. First, estimated values of Φ_t are computed from (6) as

$$\hat{\phi}_t = \hat{y}_t - \hat{\beta}_l l_t. \quad (9)$$

Then for a candidate value β_k^* it is possible to calculate (up to a constant) a prediction of ω_t using

$$\hat{\omega}_t = \hat{\phi}_t - \beta_k^* k_t. \quad (10)$$

A consistent non-parametric approximation to $E[\omega_t | \omega_{t-1}]$ is given by the predicted values from the regression

$$\hat{\omega}_t = \gamma_0 + \gamma_1 \omega_{t-1} + \gamma_2 \omega_{t-1}^2 + \gamma_3 \omega_{t-1}^3 + \mathcal{G}_t \quad (11)$$

which is called $\hat{E}[\omega_t | \omega_{t-1}]$. Given $\hat{\beta}_l, \beta_k^*$, and $\hat{E}[\omega_t | \omega_{t-1}]$, the estimate of β_k is defined as a solution to the minimization of the squared sample residuals

$$\min_{\beta_k^*} \sum_t \left(y_t - \hat{\beta}_l l_t - \hat{\beta}_k^* k_t - \hat{E}[\omega_t | \omega_{t-1}] \right)^2. \quad (12)$$

Finally, a bootstrap based on random sampling from observations is used to construct standard errors for the estimates of β_l and β_k .

Levinsohn and Petrin assume that given the quasi-fixed capital, the firm decides on labor and then, given the labor, determines the use of material input. On the other hand, Akerberg et al. (2006) argue that decisions on labor l_t and intermediate input m_t are taken simultaneously, so that the approach of Levinsohn and Petrin suffers from collinearity problems. Given that (2) holds, labor may also be chosen as $l_t = h(k_t, \omega_t)$. While h is a different function than f , substituting (3) yields $l_t = h(k_t, g(k_t, m_t)) = i(k_t, m_t)$. Labor is thus a function of capital and material input, invalidating the identification of the labor coefficient in the first step.⁷

Instead of a two-step approach, Wooldridge (2009) proposes to estimate β_l and β_k in one step. Given a production function (1), assume that the error term ε_t is uncorrelated with labor, capital, and material input as in (7), but also with all lags of these:

$$E(\varepsilon_t | l_t, k_t, m_t, l_{t-1}, k_{t-1}, m_{t-1}, \dots, l_1, k_1, m_1) = 0. \quad (13)$$

Another assumption in Wooldridge (2009) is to restrict the dynamics of unobserved productivity shocks as

$$E(\omega_t | k_t, l_{t-1}, k_{t-1}, m_{t-1}, \dots) = E(\omega_t | \omega_{t-1}) = j(\omega_{t-1}) = j(g(k_{t-1}, m_{t-1})), \quad (14)$$

where $\omega_{t-1} = g(k_{t-1}, m_{t-1})$ is used. Now for productivity innovations a_t we can write

$$\omega_t = j(\omega_{t-1}) + a_t, \quad (15)$$

where

$$E(a_t | k_t, l_{t-1}, k_{t-1}, m_{t-1}, \dots, l_1, k_1, m_1) = 0. \quad (16)$$

Variable inputs l_t and m_t are thus correlated with productivity innovations a_t , but capital k_t and all past values of l_t , m_t , and k_t are uncorrelated with a_t . Substituting (15) and (14) into (1) yields

$$y_t = \beta_0 + \beta_l l_t + \beta_k k_t + j(g(k_{t-1}, m_{t-1})) + u_t, \quad (17)$$

where $u_t = a_t + \varepsilon_t$ and

$$E(u_t | k_t, l_{t-1}, k_{t-1}, m_{t-1}, \dots, l_1, k_1, m_1) = 0. \quad (18)$$

To estimate β_l and β_k , we need to specify the functions g and j in (17). Similarly as Levinsohn and Petrin, we may consider low-degree polynomials in the function g of order up to three. In (15), we may assume that the productivity process is a random walk with drift, so that (15) becomes

$$\omega_t = \tau + \omega_{t-1} + a_t. \quad (19)$$

Plugging (19) and $\omega_{t-1} = g(k_{t-1}, m_{t-1})$ into (1) yields

$$y_t = (\beta_0 + \tau) + \beta_l l_t + \beta_k k_t + g(k_{t-1}, m_{t-1}) + u_t, \quad (20)$$

⁷ Akerberg et al. (2006) propose an alternative approach that is still a two-step one, but unlike in Levinsohn and Petrin (2003), the production function parameters are identified in the second step.

where $u_t = a_t + \varepsilon_t$ and (18) holds.

Equation (20) with polynomials in k_{t-1} and m_{t-1} of order up to three approximating for the function g could be estimated using pooled IV, using $k_t, l_{t-1}, m_{t-1}, k_{t-1}$, and polynomials containing m_{t-1} and k_{t-1} of order up to three as instruments for l_t .⁸ Given (16), this approach is robust to the Akerberg et al. (2006) critique and unlike in Levinsohn and Petrin, bootstrapping is not required to obtain robust standard errors.

While value added, labor, and intermediate input are provided in the data for the identification of production functions, another problem is the measurement error in capital in equation (1), yielding biased production function estimates. In particular, the capital coefficient is attenuated toward zero (see Levinsohn and Petrin, 2003). Hence, we have to acknowledge that capital is measured with an error and one has to use a method that explicitly takes such data properties into account.

To account for the measurement error in capital, we modify the Levinsohn-Petrin routine in the first stage, where we use instrumental variable regression instead of ordinary least squares in (5), employing appropriate instruments for capital. In particular, given the iid measurement error e_t , the true values of capital $\hat{k}_t = k_t - e_t$ are obtained as predicted values from the OLS estimation of

$$k_t = \gamma_0 + \gamma_1 z_{1t} + \dots + \gamma_N z_{Nt} + e_t, \quad (21)$$

where z_{1t}, \dots, z_{Nt} are determinants (instruments) of capital and γ_0 is a firm-specific fixed effect. Equation (5) then becomes

$$y_t = \beta_0 + \beta_k \hat{k}_t + \beta_l l_t + g(\hat{k}_t, m_t) + \varepsilon_t, \quad (22)$$

where

$$E(e_t | \varepsilon_t) = 0. \quad (23)$$

When higher-order polynomials are used in place of g in (22), the first-step estimates in the Levinsohn and Petrin approach are not consistent.⁹ However, this can be solved by using linear approximation of g , which we use in one set of our results.

In the second stage, we use the predicted values of capital, so that (12) becomes

$$\min_{\beta_k^*} \sum_t \left(y_t - \hat{\beta}_l l_t - \hat{\beta}_k^* \hat{k}_t - \hat{E}[\omega_t | \omega_{t-1}] \right)^2. \quad (24)$$

Finally, we derive the standard errors of the coefficient estimates using a non-parametric bootstrap. While the Levinsohn-Petrin routine samples with replacement from firms and derives

⁸ This approach is used in Petrin and Levinsohn (2011). In fact, Wooldridge (2009) proposes to estimate equations (5) and (17) in a generalized method of moments framework as a two-equation system with the same dependent variable and with different sets of instruments. He argues that two-step estimators like Levinsohn and Petrin (2003) are inefficient because contemporaneous correlation in the errors across the equations is ignored and because serial correlation and heteroskedasticity are not efficiently controlled for.

⁹ To see the point, consider $g = d_1(k_t - e_t) + d_2(k_t - e_t)^2 + d_3(k_t - e_t)^3$. Then $E(k_t - e_t)^2 \neq E^2(k_t - e_t)$ and $E(k_t - e_t)^3 \neq E^3(k_t - e_t)$ when \hat{k}_t is used instead of k_t in the estimation of (5).

estimates of the standard errors from the variation in the coefficient estimates across the bootstrapped samples, we sample the observations from a distribution that reflects the uncertainty in the capital value. In particular, the capital values for each firm are drawn with 100 replications from a distribution $\hat{k}_t + \eta_t$, where \hat{k}_t is the predicted capital (including the fixed effect) from the regression (21) and $\eta_t \sim N(0, \sigma_k^2)$. The parameter σ_k^2 is the firm-specific variance of predicted capital \hat{k}_t obtained by bootstrap with 1,000 replications.¹⁰

In the Wooldridge (2009) approach, the correction for measurement error in capital is straightforward. In particular, we have to find appropriate instruments for capital k_t in (20). In the estimation, we use the same instruments for capital as in our modified LP approach.

3. Data Description

We estimate firm-level production functions for 2-digit NACE level manufacturing industries (excluding petroleum and refining) using a large panel of Czech manufacturing firms with 20 or more employees in 2002–2007 containing balance sheet and income statement information gathered by the Czech Statistical Office. While the dataset contains mainly financial variables, we complement the dataset with firm-level information on material consumption in physical units from the Czech Statistical Office. The advantage of our data compared to Levinsohn and Petrin (2003) and Wooldridge (2009) is that all intermediate inputs are reported in physical units so that there is no (even potential) problem with prices and deflating.¹¹

Our sample covers economically active firms with non-zero electricity consumption and non-zero employment in each year and without organizational changes such as mergers and acquisitions. In the dataset, we imputed missing values as averages of adjacent observations.¹² The number of observations across industries and summary statistics are illustrated in Table 1. The real value added growth in manufacturing industries is displayed in Figure 1. It is derived from the sample as the weighted sum of year-on-year growth in firms' real value added.

¹⁰ The sampling is thus performed twice. First, the firm-specific variance of the predicted capital is obtained, and, second, standard LP sampling is done where capital is randomly drawn from the distribution reflecting the firm-specific variance of the predicted capital.

¹¹ The dataset used in the estimation is unbalanced, which accounts for firms' death and attrition. As firms' exit depends on their productivity, there is a sample selection bias when using balanced panels. Olley and Pakes (1996) show that using the full sample instead of the balanced panel leads to more plausible production function estimates.

¹² This accounts for about 6% of all the observations. Our results are robust when these observations are dropped from the sample.

Table 1: Summary Statistics

	N	Mean	Std. Dev.
<i>Manufacture of food products, beverages and tobacco products (NACE 15–16)</i>			
Log real value added	1510	10.384	1.305
Log hours worked	1510	12.164	0.983
Log capital	1510	10.709	1.671

4. Estimation Results

When using balance sheets or other data, one has two competing options for calculating value added. The accounting measure is the sum of the firm's sales, stocks, and new investments minus intermediate inputs and sales and services costs. As the balance sheets contain undefined values for some variables, there is high portion of missing values. As an alternative, the value added may be defined as an economic proxy utilizing the firm's profit, depreciation, and wage bill. As the results do not differ qualitatively, we further limit ourselves to the precise accounting measure of value added described above. This is accompanied by 2-digit NACE deflators of value added obtained from the Czech Statistical Office.

The main contribution of our paper concerns the issue of capital measurement. Capital is defined as the sum of tangible and intangible assets at the beginning of the period, net of depreciation. In essence, as the capital is measured using historical book value, one has to account for measurement error. As the capital deflator we use the average inflation rate, or, alternatively, the interest rate of new borrowing, which reflects the cost of capital, to verify whether the definition of the discount factor matters in the estimation.¹³

As a freely available input factor for production, we use the number of hours worked. As a proxy for unobserved productivity shocks we use the consumption of electricity in physical units (MWh). Depreciation, the full-time equivalent of the average number of employees, and gas consumption in physical units are used as available instruments for capital.

The results by industries in 2003–2007 are summarized in Table 2. The first estimation (column 1) uses the Wooldridge (2009) approach where real capital (deflated by the inflation rate)¹⁴ is instrumented using depreciation, employment, and gas consumption in physical units as instruments. In column 2, the Wooldridge (2009) estimates are reported assuming that real capital is exogenous. Comparing columns 1 and 2, we see that correcting for capital measurement error significantly increases the coefficient estimate of capital.

In column 3 we show the production function estimates using the LP method as implemented in Stata. In general, except for two industries (rubber and plastic products – NACE 25; other manufacturing – NACE 36–37) we do not observe a significant difference between columns 2 and 3. The estimation using Wooldridge (2009) thus yields similar results to Levinsohn and Petrin (2003), while the Wooldridge (2009) estimates are robust to the Akerberg et al. (2006) critique. Without the measurement error in capital, both methods thus yield quantitatively similar results.

¹³ A significant amount of literature deals with the issue of using the right discount factor for capital; see, for example, Levinsohn and Petrin (2003).

¹⁴ We also used the interest rate of new borrowing as an alternative capital deflator. The results are similar and are available from the authors on request.

- (6) Levinsohn-Petrin (2003); real capital is instrumented using depreciation, employment, and gas consumption; linear approximation used in (6).

In column 4 of Table 2, we use the LP method with correction for the measurement error in real capital. In particular, we estimate (21) using OLS and generate predicted values of capital that are then used as the capital data input to the LP method. The modified non-parametric bootstrap is employed to get corrected standard errors of the coefficients.

As in the Wooldridge (2009) approach (columns 1 and 2), we observe a major difference between columns 4 and 3 in Table 2 in all industries except for manufacture of wood (NACE 20–22); the coefficient associated with real capital often more than double, while the changes in the labor coefficient estimates are minor.¹⁵ Based on our results using the Wooldridge (2009) and Levinsohn and Petrin (2003) approaches we see that measurement error in capital is a substantial problem that affects production function estimates. Not accounting for the measurement error in capital yields an estimate biased toward zero.

As we have shown in Section 2, using predicted values of real capital in the first stage of the LP routine yields inconsistent estimates. We therefore repeat the estimation in columns 3 and 4 in Table 2, assuming linear approximation in place of the function g in equations (5) and (22). The results of this exercise are reported in columns 5 and 6 in Table 2. The difference in the coefficient estimates between columns 3 and 5 and between columns 4 and 6 is small in most industries, suggesting that measurement error in capital affects the estimates more than specific assumptions approximating the unknown function g in equations (5) and (22).

The correction for measurement error of capital affects returns to scale. Table 3 repeats the returns to scale estimates from columns 1–4 in Table 2 for manufacturing industries. While most industries using the standard methods of Wooldridge (2009) and Levinsohn and Petrin (2003) exhibit constant or decreasing returns to scale (see columns 2 and 3 in Table 3), we cannot reject the presence of increasing returns in a number of industries when the estimation is corrected for measurement error in capital (columns 1 and 4). The difference in the results hinges on the correction of measurement error in capital, while the degree of the polynomial used in the estimation does not play a crucial role.

¹⁵ Similar results are obtained when using gas consumption as a proxy to invert out the unobserved productivity shock in the LP routine and electricity consumption as an instrument for real capital. These alternative results are available from the authors upon request.

5. Conclusions

Based on our results we conclude that the measurement error of capital is a substantial problem that affects production function estimates. The estimated capital coefficient approximately doubles (depending on the particular industry) when we control for capital measurement error. The estimated standard errors of the coefficients naturally also increase when measurement error in capital is assumed, although the difference in the coefficients is so substantial that one can reject the identity of the coefficient with and without measurement error control. Consequently, while the majority of industries using standard Wooldridge (2009) and Levinsohn and Petrin (2003) estimation exhibit constant or (in)significantly decreasing returns to scale, measurement error correction sometimes leads to a situation where even increasing returns to scale cannot be rejected.

To sum up, we conclude that an estimation that ignores possible measurement error in capital might suffer from significant underestimation of the effect of capital on value added formation and that the contribution of capital to value added growth in Czech manufacturing industries was probably higher in 2003–2007 than based on estimates without controlling for measurement error in capital.

CNB WORKING PAPER SERIES

9/2011	Kamil Galuščák Lubomír Lízal	<i>The impact of capital measurement error correction on firm-level production function estimation</i>
8/2011	Jan Babecký Tomáš Havránek Jakub Matějů Marek Rusnák Kateřina Šmídková Bořek Vašíček	<i>Early warning indicators of economic crises: Evidence from a panel of 40 developed countries</i>
7/2011	Tomáš Havránek Zuzana Iršová	<i>Determinants of horizontal spillovers from FDI: Evidence from a large meta-analysis</i>
6/2011	Roman Horváth Jakub Matějů	<i>How are inflation targets set?</i>
5/2011	Bořek Vašíček	<i>Is monetary policy in the new EU member states asymmetric?</i>
4/2011	Alexis Derviz	<i>Financial frictions, bubbles, and macroprudential policies</i>
3/2011	Jaromír Baxa Roman Horváth Bořek Vašíček	<i>Time-varying monetary-policy rules and financial stress: Does financial instability matter for monetary policy?</i>
2/2011	Marek Rusnák Tomáš Havránek Roman Horváth	<i>How to solve the price puzzle? A meta-analysis</i>
1/2011	Jan Babecký Aleš Bulíř Kateřina Šmídková	<i>Sustainable real exchange rates in the new EU member states: What did the Great Recession change?</i>
15/2010	Ke Pang Pierre L. Siklos	<i>Financial frictions and credit spreads</i>
14/2010	Filip Novotný Marie Raková	<i>Assessment of consensus forecasts accuracy: The Czech National Bank perspective</i>
13/2010	Jan Filáček Branislav Saxa	<i>Central bank forecasts as a coordination device</i>
12/2010	Kateřina Arnoštová David Havrlant Luboš Růžička Peter Tóth	<i>Short-term forecasting of Czech quarterly GDP using monthly indicators</i>
11/2010	Roman Horváth Kateřina Šmídková Jan Zápál	<i>Central banks' voting records and future policy</i>
10/2010	Alena Bičáková Zuzana Prelcová Renata Pašaličová	<i>Who borrows and who may not repay?</i>
9/2010	Luboš Komárek Jan Babecký Zlataše Komárková	<i>Financial integration at times of financial instability</i>
8/2010	Kamil Dybczak Peter Tóth David Voňka	<i>Effects of price shocks to consumer demand. Estimating the QUAIDS demand system on Czech Household Budget Survey data</i>
7/2010	Jan Babecký Philip Du Caju	<i>The margins of labour cost adjustment: Survey evidence from European Firms</i>

	Theodora Kosma Martina Lawless Julián Messina Tairi Rõõm	
6/2010	Tomáš Havránek Roman Horváth Jakub Matějů	<i>Do financial variables help predict macroeconomic environment? The case of the Czech Republic</i>
5/2010	Roman Horváth Luboš Komárek Filip Rozsypal	<i>Does money help predict inflation? An empirical assessment for Central Europe</i>
4/2010	Oxana Babecká Kucharčuková Jan Babecký Martin Raiser	<i>A Gravity approach to modelling international trade in South- Eastern Europe and the Commonwealth of Independent States: The role of geography, policy and institutions</i>
3/2010	Tomáš Havránek Zuzana Iršová	<i>Which foreigners are worth wooing? A Meta-analysis of vertical spillovers from FDI</i>
2/2010	Jaromír Baxa Roman Horváth Bořek Vašíček	<i>How does monetary policy change? Evidence on inflation targeting countries</i>
1/2010	Adam Geršl Petr Jakubík	<i>Relationship lending in the Czech Republic</i>
15/2009	David N. DeJong Roman Liesenfeld Guilherme V. Moura Jean-Francois Richard Hariharan Dharmarajan	<i>Efficient likelihood evaluation of state-space representations</i>
14/2009	Charles W. Calomiris	<i>Banking crises and the rules of the game</i>
13/2009	Jakub Seidler Petr Jakubík	<i>The Merton approach to estimating loss given default: Application to the Czech Republic</i>
12/2009	Michal Hlaváček Luboš Komárek	<i>Housing price bubbles and their determinants in the Czech Republic and its regions</i>
